**Abstract:** The pH titration studies (pH 6.7–12.1) in a series of dimeric, trimeric, tetrameric, pentameric, and hexameric oligo-RNA molecules [GpA (**2a**), GpC (**3a**), GpApC (**5**), GpA<sup>1</sup>pA<sup>2</sup>pC (**6**), GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pC (**7**), GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pA<sup>4</sup>pC (**8**)] have shown that the  $pK_a$  of  $N^1$ -H of 9-guaninyl could be measured not only from its own  $\delta$ H8G, but also from the aromatic marker protons of other constituent nucleobases. The relative chemical shift differences [ $\Delta\delta_{(N-D)}$ ] between the protons in various nucleotide residues in the oligo-RNAs at the neutral (N) and deprotonated (D) states of the guanine moiety show that the generation of the 5'-(9-guanylate ion) in oligo-RNAs **2–8** reduces the stability of the stacked helical RNA conformation owing to the destabilizing anion( $G^-$ )– $\pi$ /dipole( $Im^{\delta-}$ ) interaction. This destabilizing effect in the deprotonated RNA is, however, opposed by the electrostatically attractive atom– $\pi\sigma$  (major) as well as the anion( $G^-$ )– $\pi$ /dipole-( $Py^{\delta+}$ ) (minor) interactions. Our studies have demonstrated that the electrostatically repulsive anion( $G^-$ )– $\pi$ /dipole( $Im^{\delta-}$ ) interaction propagates from the first to the third nucleobase quite strongly in the oligo-RNAs **6–8**, causing destacking of the helix, and then its effect is gradually reduced, although it is clearly NMR detectable along the RNA chain. Thus, such specific generation of a charge at a single nucleobase moiety allows us to explore the relative strength of stacking within a single-stranded helix. The  $pK_a$  of 5'-Gp residue from its own  $\delta$ H8G in the hexameric RNA **8** is found to be  $9.76 \pm 0.01$ ; it, however, varies from 9.65  $\pm$  0.01 to 10.5  $\pm$  0.07 along the RNA chain as measured from the other marker protons (H2, H8, H5, and H6) of 9-adeninyl and 1-cytosinyl residues. This nucleobase-dependent modulation of  $pK_a$ s ( $\Delta pK_a \pm 0.9$ ) of 9-guaninyl obtained from other nucleobases in the hexameric RNA **8** represents a  $\Delta G_{pK_a}^{\circ}$  difference of ca. 5.1 kJ mol<sup>-1</sup>, which has been attributed to the variable strength of electrostatic interactions between the electron densities of the involved atoms in the offset stacked nucleobases as well as with that of the phosphates. The chemical implication of this variable  $pK_a$  for guanin-9-yl deprotonation as obtained from all other marker protons of each nucleotide residue within a ssRNA molecule is that it enables us to experimentally understand the variation of the electronic microenvironment around each constituent nucleobase along the RNA chain in a stepwise manner with very high accuracy without having to make any assumption. This means that the pseudoaromaticity of neighboring 9-adeninyl and next-neighbor nucleobases within a polyanionic sugar–phosphate backbone of a ssRNA can vary from one case to another due to cross-modulation of an electronically coupled  $\pi$  system by a neighboring nucleobase. This modulation may depend on the sequence context, spatial proximity of the negatively charged phosphates, as well as whether the offset stacking is ON or OFF. The net outcome of this electrostatic interaction between the neighbors is creation of new sequence-dependent hybrid nucleobases in an oligo- or polynucleotide whose properties are unlike the monomeric counterpart, which may have considerable biological implications.

### Introduction

The self-assembly process of DNA and RNA is mainly dictated by stacking and hydrogen-bonding interactions. Stacking interactions between two neighboring nucleobases stabilize the DNA or RNA helix<sup>1a,2</sup> by ca. 0.4–3.6 kcal mol<sup>-1</sup>, whereas H-bonding promoted stabilization can vary from 0.5 to 2 kcal mol<sup>-1</sup> per H bond.<sup>1</sup> It is, however, the stacking interaction that

plays a more important role in the self-assembly of the single-stranded RNA structures, which is important for both the

recognition and interaction with many ligands including proteins. A single dangling nucleotide<sup>2a-d</sup> at the end of both DNA and RNA duplexes is known to increase the duplex stability. In more recent studies,<sup>2e</sup> it has been shown that longer single-stranded dangling residues (up to tetranucleotide) stabilize the RNA–RNA and DNA–DNA duplexes even slightly more (by an extra  $\sim 0.1–1.0$  kcal mol<sup>-1</sup>) than the single-nucleotide dangling end, which is reported to be  $\sim 2.0$  kcal mol<sup>-1</sup>. This enhanced stability arising from the long dangling ends originates from the single-stranded stacking interaction. The biological importance of the dangling nucleotides in RNA function is quite ubiquitous: the dangling 5'-ACCA-3' at the 3'-terminus of tRNA orchestrates the aminoacylation reaction for protein synthesis in the ribosome. The high fidelity of this protein synthesis in the ribosome is dictated by the specific codon–anticodon interaction between mRNA and tRNA, which is stabilized by the dangling ends. It has also been shown<sup>2e</sup> that 2–3nt dangling ends are important for the RNAi functionality. A dangling nucleotide at the 3'-end of a pseudoknot RNA is also known to stabilize the stem structure. Recently, it has been demonstrated that single unpaired base bulges in RNA duplexes enhance the stability of the RNA more compared to the fully base-paired counterpart, in which both the base identity as well as the nearest-neighbor context have been shown to be important for the overall relative stability of the bulges.

Although much is known in qualitative terms about the ubiquitous role of stacking in dictating the geometry and function of nucleic acids in general,<sup>13</sup> very little direct experimental evidence is available on the molecular nature of stacking interactions.

More direct experimental evidences are, however, available from the studies of aromatic interactions in the nonbiological systems,<sup>5–7</sup> which are of considerable fundamental interest in understanding molecular recognition and in the modeling of the biological functionalities. The major noncovalent aromatic interactions (mostly in nonbiological model systems) so far identified can be categorized as (i)  $\pi$ – $\pi$  interaction [face-to-face, edge-to-face (T-shaped), and offset (atom– $\pi$ )],<sup>5,6</sup> (ii) CH– $\pi$  interaction (involving CH of both aryl<sup>6c,e–g</sup> and alkyl<sup>7i,8c</sup>), and (iii) ion– $\pi$  interaction (involving both cation– $\pi$ <sup>7h</sup> as well as anion– $\pi$ <sup>10</sup>).

Evidences regarding the nature of intramolecular aromatic interactions in nucleic acids and their complexes<sup>3,8</sup> have mainly come from various structural studies: Thus, Hunter et al. first invoked the presence of offset stacked nucleobases in DNA<sup>5a,b</sup> based on the X-ray crystallographic data followed by computer modeling to construct conformation-dependent energy maps based on van der Waals and electrostatic interactions calculated between stacked bases. Rooman et al.<sup>8b</sup> defined and analyzed stair-shaped motifs, which simultaneously involve base stacking, hydrogen bond, and cation– $\pi$  interaction in protein–DNA complexes through the geometrical proximity found in the X-ray crystallographic database. Recent database studies<sup>8c</sup> showed the importance of thymine–methyl/ $\pi$  interaction in the sequence-dependent deformability of DNA. Moreover, studies based on screening of nucleic acid databases showed that divalent cations

[like Mg(OH<sub>2</sub>)<sub>6</sub><sup>2+</sup>] interact favorably with  $\pi$  systems of nucleic acid bases.<sup>8a</sup> Thus, the hydrated magnesium ions located in the major groove of B-DNA pull cytosine bases partially out from the helical stack, exposing  $\pi$  systems to positive charge. It is also found that some critical cation– $\pi$  interactions contribute to the stability of the anticodon arm of yeast tRNA<sup>phe</sup> and to the magnesium core of the Tetrahymena group I intron P4–P6

M.; Sandström, A.; Zarytova, V. F.; Chattopadhyaya, J. *Nucleic Acids Res.* **1994**, *22*, 5590. (c) Ossipov, D.; Pradeepkumar, P. I.; Holmer, M.; Chattopadhyaya, J. *J. Am. Chem. Soc.* **2001**, *123*, 3551. (d) Acharya, S.; Acharya, P.; Földesi, A.; Chattopadhyaya, J. *J. Am. Chem. Soc.* **2002**, *124*, 13722. (e) Acharya, P.; Acharya, S.; Földesi, A.; Chattopadhyaya, J. *J. Am. Chem. Soc.* **2003**, *125*, 2094. (f) In our earlier study (ref 4e) with the dimer (GpA, **2a**) and the trimers, GpApA (**4**) and GpApC (**5**), we found that none of the H2A showed any appreciable chemical shift change as a function of pH ( $\Delta\delta_{N-D}$ ), except for H2A of pAp of **4**, which became clearly shielded, whereas all H8 were deshielded because of destacking (see Figure 3 of this paper). This H2A shielding was explained on the basis of a T-shaped interaction between the pyrimidine of pAp and the 9-guaninyl ion in ref 4e. The review of the data in context with the larger oligo-RNAs (Figure 3 of this paper), however, suggests that we cannot rule out an attractive atom– $\pi$  and anion(G<sup>-</sup>)– $\pi$ /dipole–(Py<sup>b+</sup>) interaction for the pyrimidine of pA'p of **4** and the 9-guaninyl ion interaction causing shielding of H2A of pAp of **4**, whereas the deshielding of H8A can be explained by a destacking owing to anion(G<sup>-</sup>)– $\pi$ /dipole–(Im<sup>b+</sup>) repulsion. (g) The electrostatic/charge-transfer interaction (or donor–acceptor properties) has been invoked to explain the observed results in the pH-dependent studies of dimeric RNA.<sup>4d</sup> However, the present study on oligo-RNAs of various chain lengths points to the fact that electrostatics is the dominant component in these base–base interactions in both neutral and ionic states. Observation of modulation of  $pK_a$  of 9-guaninyl from the marker protons of the neighboring bases (refs 4d,e and this paper), however, suggests a possible contribution of charge transmission between them (but no charge-transfer band in UV is, however, found). Thus, it is not possible at this stage to delineate the relative contribution of electrostatic and nonelectrostatic components in our observed overall interactions in RNA. There are two primary reasons for this: (i) our RNA system is too large for a high basis-set ab initio optimization, no well-defined starting geometry of ssRNA is available for this purpose, and (ii) we cannot use any other solvent but water for solubility reasons for examining the relative contribution of electrostatics as delineated in earlier studies.<sup>6h,i</sup> The study of the effect of salt concentration, however, may allow us (although it is known to be minimal for single-strand nucleic acid stacking<sup>1b</sup>) to dissect the origin of electrostatics vs unusual  $pK_a$  values from various factors such as hydrogen bond, charge–charge interaction, and the degree of solvent exposure of the charged group.<sup>4h–j</sup> (h) Song, J.; Laskowski, M., Jr.; Qasim, M. domain. Such cation- $\pi$  interactions have been also implicated in DNA bending, DNA-protein recognition, base-flipping, RNA folding, and catalysis.<sup>8a</sup> Ab initio studies have shown the presence of the aromatic interactions (mostly of cation- $\pi$  in nature)<sup>8i</sup> between protein and DNA involving positively charged Arg or Lys side chains and aromatic rings of nucleic acids. The X-ray studies along with calorimetric and fluorescence analyses

have shown<sup>3</sup> the importance of electrostatic cation- $\pi$  interaction in the protein recognition of the m<sup>7</sup>G part of the mRNA cap structure. Similar kinetic and calorimetric experiments<sup>8e</sup> have also identified the key aromatic  $\pi$ - $\pi$  stacking interaction between Tyr41 and the adenine ring of bound nucleotides in the active site of an aminoglycoside phosphotransferase enzyme.

Our studies,<sup>4d,e</sup> on the other hand, deal with the experimental demonstration of the ubiquitous electrostatic interactions among the nearest-neighbor pseudoaromatic nucleobases in oligo-RNA in both the neutral as well as the ionic states, modeling ligand binding to nucleic acid bases. The pH-dependent NMR studies<sup>4d</sup> of di-ribonucleoside (3'  $\rightarrow$  5') monophosphates compared to their corresponding monomers showed that each nucleobase in a dimer not only shows its own  $pK_a$  but also that of the neighboring nucleobase, owing to the cross-modulation of each other's pseudoaromatic character in an electronically coupled  $\pi$  system via intramolecular electrostatic interaction through offset stacking. Thus, the physicochemical comparison, for example, of the GpA/G<sup>-</sup>pA and ApG/ApG<sup>-</sup> showed the nature of atom- $\pi$ <sup>5,9</sup> versus anion- $\pi$ <sup>10</sup> interactions, whereas the comparison in the two isomeric dimers<sup>4d,f</sup> in the neutral, anionic, and cationic states [UpA/U<sup>-</sup>pA/UpA<sup>H+</sup> and ApU/ApU<sup>-</sup>/A<sup>H+</sup>-pU, or UpC/U<sup>-</sup>pC/UpC<sup>H+</sup> and CpU/CpU<sup>-</sup>/C<sup>H+</sup>pU] showed direct evidence<sup>4g</sup> of the electrostatic interaction between the neighboring nucleobases (atom- $\pi$ <sup>5</sup> in the neutral state, anion- $\pi$ <sup>10</sup> in the deprotonated state vs cation- $\pi$ <sup>7g,h</sup> in the protonated state) as a result of intramolecular offset stacking. This electrostatic interaction leads to almost total modulation of the pseudoaromaticity by nearly total transmission of  $\Delta G_{pK_a}^{O, 14a-c,f-i}$  from one nucleobase to the nearest neighbor (16–53 kJ mol<sup>-1</sup>, depending upon whether the nucleobase is at the cationic or anionic state). This suggested that the nucleobase in a stacked dinucleotide, unlike simple monomers, constitutes an electronically coupled heterocyclic system. Similarly, we demonstrated<sup>4e</sup> the existence of this electrostatic nearest-neighbor interaction between the first and third nucleobases in tri-ribonucleoside (3'  $\rightarrow$  5') diphosphates with  $\Delta G_{pK_a}^{O}$  transmission from the 5'-guanylate ion to the 3'-end nucleobase via the central adenin-9-yl, 55–56 kJ mol<sup>-1</sup> in each step through a distance spanning  $\sim 6.8$  Å in an unfolded state. As a result, we found<sup>4e</sup> that the  $pK_a$  of guanin-9-yl moiety has become  $9.25 \pm 0.02$  in GpEt (**1a**),  $9.17 \pm 0.02$  in GpA (**2a**),  $9.75 \pm 0.02$  in GpApA (**3**), and  $9.88 \pm 0.03$  in GpApC (**4**), which meant that the 9-guaninyl moiety of trimers is more basic than that in the monomer or in the dimer because of both the neighboring nucleobases and the phosphate(s).

Here we show that the stabilizing electrostatic atom- $\pi$ <sup>5</sup> interaction,<sup>5</sup> indeed, extends from the first to the sixth nucleotide in a single-stranded hexameric RNA, which is  $\sim 21$  Å apart in the unfolded neutral state. We also present evidence showing that, in the deprotonated state, the stability of the stacked helical

- (9) The intra- and intermolecular stacking and/or other aromatic interactions<sup>5–8</sup> involving both biological as well as nonbiological systems has been shown to be a major force in molecular recognition and biological functionalities. The aromatic stacking interaction between nucleobases<sup>2b</sup> in water has been implicated to electrostatic effects (dipole-dipole and dipole-induced dipole) interactions, dispersion (momentary dipole-induced dipole), and solvation. Hunter et al.<sup>5</sup> invoked offset stacking involving attractive atom- $\pi$  interaction (electrostatic in nature) and edge-to-face interactions (same as center-to-edge termed by Siegel et al.<sup>6e</sup>) rather than energetically unfavorable  $\pi$ - $\pi$  interaction as in face-to-face stacking between two aromatic moieties. In both offset stacking and edge-to-face interactions, the CH group of the edge ring and the electron density of the face ring are sensitive to changes in the local charge (partial charge) distribution of the two rings.<sup>5c,6g</sup> However, unlike offset stacking, edge-to-face interaction is considered as weak noncovalent through-space aromatic interaction, not any stacking interaction.<sup>6a</sup> Theoretical studies<sup>7b</sup> recently showed that dispersion effects other than electrostatics dominate both aryl CH- $\pi$ , and alkyl CH- $\pi$  interactions. In all cases alkyl CH- $\pi$  interactions are weaker than aryl CH- $\pi$  interactions. Nishio et al.<sup>7i</sup> proposed partial charge transfer arising from through-space proximity between alkyl hydrogen and aromatic moiety as the basis for CH- $\pi$  interaction. On the other hand, Siegel et al.<sup>6e–g</sup> and Diedrich et al.<sup>7j</sup> proposed a through-space polar (Coulombic)/ $\pi$  contribution as a dominating factor in the electrostatic interactions involved in edge-to-face as well as the center-to-edge (i.e., offset) oriented aromatic moieties in the neutral<sup>7e</sup> as well as in the ionic states (such as carboxylate ion/arene<sup>7f</sup> and trimethylammonium ion/arene<sup>7i</sup> interaction). Moreover, Dougherty et al. showed<sup>7g,h</sup> that both electrostatic and polarization effects are dominant contributions in the cation- $\pi$  interaction, which have been shown<sup>8f–h</sup> to make a significant contribution in the stabilization of  $\alpha$ -helical peptides in aqueous solution. Recent works have also shown theoretical evidences<sup>10</sup> of anion- $\pi$  interactions.
- (10) (a) Recent studies<sup>10a–d</sup> invoked a weak noncovalent attractive anion- $\pi$  interaction involving the negatively charged  $\pi$  cloud of unsubstituted benzene ring and positively charged  $\sigma$  framework of the hexafluorobenzene (C<sub>6</sub>F<sub>6</sub>). However, recent studies<sup>10f</sup> proposed an anion-arene interaction having both a positive as well as a negative component. **Figure 1.** Compounds used in this study: GpA (2a), ApG (2b), GpC (3a), CpG (3b), GpApA (4)<sup>de</sup> (not shown), GpApC (5), GpA<sup>1</sup>pA<sup>2</sup>pC (6), GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pC (7), and GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pA<sup>4</sup>pC (8) and their monomeric counterparts GpEt (1a), 3'-GMP (1b), 5'-GMP (1c), EtpGpEt (1d), 5'-EtpG (1e), EtpApEt (1f), and 5'-EtpC (1g). Note monomeric compounds 1a–f are used as reference compounds to evaluate the relative stacking in oligo-RNAs 2a–8.

RNA conformation is reduced by the destabilizing anion( $G^-$ )– $\pi$ /dipole( $Im^{\delta-}$ ) interaction owing to the generation of the 5'-(9-guanylate ion) (for terminologies used in various electrostatic interactions, see ref 9). This destabilizing effect in the deprotonated RNA is, however, opposed by the attractive atom– $\pi\sigma$  interaction (major) as well as the minor anion( $G^-$ )– $\pi$ /dipole-( $Py^{\delta+}$ ) interactions.

## Results and Discussion

**(A) Effect of Generation of the 5'-Guanylate Ion and Its Electrostatic Modulation in the Hexameric ssRNA.** The pH titration studies (pH 6.7–12.1) in a series of dimeric, trimeric, tetrameric, pentameric, and hexameric single stranded (ss) oligo-RNA molecules [GpA (2a), GpC (3a), GpA<sup>1</sup>pA (4)<sup>de</sup>, GpApC

(5), GpA<sup>1</sup>pA<sup>2</sup>pC (6), GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pC (7), GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pA<sup>4</sup>pC (8)] (Figure 1) are designed such that only a single anionic species at the N<sup>1</sup> of the 9-guaninyl moiety can be generated in the alkaline pH in these RNA molecules 2–8. It is aimed to show how far the electrostatic modulation of the 9-guanylate ion in this electronically coupled system, as an interplay of Coulombic attractive or repulsive forces, propagates through the intervening pAp nucleotide moieties until the terminal pC-3' residue in comparison with the neutral counterpart. We reasoned that the footprint of this propagation of the electrostatic forces among the neighboring nucleobases will be evident by a change of the chemical environment (i.e., chemical shifts) around their aromatic marker protons ( $\delta$ H2A,  $\delta$ H8A,  $\delta$ H5C, and  $\delta$ H6C) owing to a change of the stacking orientation and/

**Figure 2.** Plot of pH-dependent ( $6.52 \leq \text{pH} \leq 12.24$ )  $^1\text{H}$  chemical shifts ( $\delta\text{H}$ ) for different aromatic protons of oligomers **6–8** showing the  $pK_a$  at the inflection point. Chemical shift variations at 28–32 different pH values have been measured in an interval of 0.2–0.3 pH units to obtain the sigmoidal curves (see Experimental Section). Each graph shows chemical shift change with pH for one particular aromatic proton in a compound. The name of the compound along with the particular aromatic proton chosen for titration, the correlation coefficient  $R$  obtained from curve fitting, and the  $pK_a$  values obtained from the Hill plot analyses are shown in the respective graphs [see Experimental Section for details and Figure S2 in the Supporting Information]. Note that in all titration curves we have taken  $\Delta\delta \approx 0.01$  ppm in order to calculate  $pK_a$ . Hence,  $pK_a$  values were not calculated for the marker protons corresponding to panels 8.4 ( $\delta\text{H8A}^3$  0.001 ppm), 8.5 ( $\delta\text{H8A}^4$  0.006 ppm), 8.8 ( $\delta\text{H2A}^3$  0.004 ppm), 8.10 ( $\delta\text{H5C}$  0.005 ppm), 7.8 ( $\delta\text{H5C}$   $-0.005$  ppm), 6.4 ( $\delta\text{H2A}^1$  0.005 ppm), and 6.5 ( $\delta\text{H2A}^2$  0.003 ppm) for which  $\Delta\delta \approx 0.01$  ppm (see Figure 3).

or planar nucleobase rotation, thereby causing a destacking and destabilization of the ssRNA helix equilibrium as the pH becomes alkaline.

(i) *pH Titration Studies.* The pH titration studies<sup>13e</sup> with the  $\text{GpA}^1\text{pA}^2\text{pA}^3\text{pA}^4\text{pC}$  (**8**) showed (Figure 2, panels 8.1–8.11) the  $pK_a$  of  $N^1\text{-H}$  of guanine-9-yl (at the 5'-end) from its own  $\delta\text{H8G}$  ( $pK_a$   $9.76 \pm 0.01$ ) as well as from  $\delta\text{H8A}^1$  ( $pK_a$   $9.65 \pm 0.01$ ) and  $\delta\text{H2A}^1$  ( $pK_a$   $9.80 \pm 0.01$ ) of the  $\text{pA}^1\text{p}$  moiety,  $\delta\text{H8A}^2$  ( $pK_a$   $9.95 \pm 0.01$ ) and  $\delta\text{H2A}^2$  ( $pK_a$   $10.5 \pm 0.07$ ) of the  $\text{pA}^2\text{p}$  moiety,  $\delta\text{H2A}^4$  ( $pK_a$   $9.66 \pm 0.01$ ) of the neighboring  $\text{pA}^4\text{p}$  moiety, and  $\delta\text{H6C}$  ( $pK_a$   $10.18 \pm 0.03$ ) of the terminal  $\text{pC-3'}$  moiety.

No significant change in the pH-dependent shift of  $\delta\text{H8A}^3$  ( $\Delta\delta$  0.001 ppm) and  $\delta\text{H2A}^3$  ( $\Delta\delta$  0.004 ppm) of the  $\text{pA}^3\text{p}$  moiety was, however, found (Figure 2, panels 8.4 and 8.8), suggesting that there is an interruption of offset stacking with its two nearest neighbors,  $\text{pA}^2\text{p}$  and  $\text{pA}^4\text{p}$ . Similarly,  $\delta\text{H8A}^4$  ( $\Delta\delta$  0.006 ppm) (but not  $\delta\text{H2A}^4$ ) and  $\delta\text{H5C}$  ( $\Delta\delta$  0.005 ppm) (but not  $\delta\text{H6C}$ ) also failed (Figure 2, panels 8.5 and 8.10) to show a titration plot, suggesting weak electrostatic interactions between electron densities of these atoms with those of the nearest-neighbor nucleobases and phosphates.

A clear-cut assessment of the strength of these weak electrostatic interactions is difficult because of the following problems: (i) the chemical shift variation is *irregular* over the pH range, (ii) the  $\Delta\delta$  values quoted above between two extreme pHs for  $\text{H8A}^4$ ,  $\delta\text{H8A}^3$ ,  $\delta\text{H2A}^3$ , and  $\text{H5C}$  of hexameric RNA in panels 8.4, 8.5, 8.8, and 8.10 are indeed very close to the experimental error ( $\pm 0.001$  ppm), (iii) if  $\Delta\delta$  is obtained between extreme pHs, it can be seen that in panels 8.4, 8.5, 8.8, and 8.10 they are indeed 2-fold less than in panel 8.11 ( $\Delta\delta$  0.01 ppm). Note that in all titration curves we have taken  $\Delta\delta \geq 0.01$  ppm in order to calculate  $pK_a$ . The possible reason for not

observing a large and/or regular change of  $\Delta\delta$  to give a pH titration curve for  $\text{H8A}^4$ ,  $\delta\text{H8A}^3$ ,  $\delta\text{H2A}^3$ , and  $\text{H5C}$  in **8** is that some of those edges or parts of the constituent nucleobases is/are relatively unstacked. Interestingly,  $\text{pA}^3\text{p}$  in **8** is perhaps fully bulged out since both its H8 and H2 remain nonresponsive over the pH range studied, although its %North (N) pseudorotamer population (see section D.iv and Figure 4) showed an increase of  $\sim 13\%$  over the pH range studied, which presumably suggests that the 9-adeninyl of  $\text{pA}^3\text{p}$  in the destacked state is taking up a relatively more pseudoaxial orientation.<sup>11c</sup> Thus, the edge(s) or part(s) of the nucleobase which might be more solvent exposed (such as  $\text{H8A}^4$  or  $\text{H5C}$ ) show larger electrostatic screening than the other edge(s) or part(s) (such as  $\text{H2A}^4$  or  $\text{H6C}$ ) of the nucleobases and, therefore, show only relatively weak electrostatic interaction with the negatively charged phosphates and the neighboring nucleobases.

The preferential atom- $\pi\sigma$  interactions,<sup>5</sup> which cause the electron densities of a specific atom (H8 over H2 in 9-adeninyl and H6 over H5 in 1-cytosinyl, see Figure 3) to interact with the nearest neighbor can also be seen through the observation of  $pK_a$  in the reference pentamer  $\text{GpA}^1\text{pA}^2\text{pA}^3\text{pC}$  (**7**) (panels 7.1–7.9) and tetramer  $\text{GpA}^1\text{pA}^2\text{pC}$  (**6**) (panels 6.1–6.7) in Figure 2, whereas the data for other reference compounds such as trimers,<sup>4e</sup> dimers,<sup>4d</sup> and monomers along with the oligo-RNAs **6–8** are summarized for comparison in Table 1.

(ii) *Variation of  $pK_a$  among Different Marker Protons.* Thus, the  $pK_a$  of 5'-Gp residue from its own  $\delta\text{H8G}$  varies only slightly (from  $9.76 \pm 0.01$  to  $9.88 \pm 0.01$ ) in the oligo-RNAs **5–8**, which should be compared with the  $pK_a$  of  $9.25 \pm 0.02$  for  $\text{GpEt}$  (**1a**),  $9.17 \pm 0.02$  for  $\text{GpA}$  (**2a**),  $9.56 \pm 0.01$  for  $\text{GpC}$  (**3a**), and  $9.45 \pm 0.02$  for  $\text{CpG}$  (**3b**) as well as  $9.57 \pm 0.01$  for 5'-EtpG (**1e**). The variation of  $pK_a$ s for 5'-Gp residue as

**The change of %N-type pseudorotamer population in the neutral (N) versus the deprotonated (D) states**

**Figure 4.** Plot of the population of the North-type conformer [%North error  $\pm$  2.0%] of the 3'-endo-2'-exo (North-type)  $\rightleftharpoons$  2'-endo-3'-exo (South-type) pseudorotational equilibrium<sup>12</sup> of the respective pentofuranose moiety in each nucleotidic unit in GpEt (**1a**), GpA (**2a**), GpC (**3a**), GpApC (**5**), GpA<sup>1</sup>pA<sup>2</sup>pC (**6**), GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pC (**7**), and GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pA<sup>4</sup>pC (**8**) at the neutral (N, shown in violet bar) and deprotonated (D, shown in red bar) states (see the table below the plot for %North-type population values at N and D states as well as the difference between these two states, i.e., D–N). The bars are in the same order as the sequence starting from 5'-Gp on the left. The  $^3J_{12'}$  values are shown in the Supporting Information. The difference between the D and the N states (D–N, shown in green bar) shows the relative stacking (increase of %North-type) or destacking (decrease of %North-type) over the pH-titration range. It can be seen from D–N values that, upon generation of the 5'-guanylate ion, the destacking takes place until the third nucleotide in the hexamer, whereas it proceeds up to the second nucleotide in the tetra- and pentamer (compare with the more sensitive  $\Delta\delta_{(N-D)}$  values in Figure 3).

9-guaninyl moiety observed from  $\delta$ H8G as well as the  $pK_a$  modulation of 5'-Gp residue observed from other marker protons of the neighboring nucleobases in the series of oligomeric RNAs **2–8**, which gives us a measure of variable pseudoaromaticity (and chemical reactivity) along the chain of a ssRNA molecule.

**(C) Tandem Electrostatic Interaction Is a Result of the Electronic Coupling of the Neighboring Nucleobases and the Phosphates. (i) Different  $pK_a$  Shift of Nucleobases due to**

(15) (a) *Comparison of  $\delta$  among Dimers:* The effect of anionic guanin-9-yl decreases (decreasing  $\Delta\delta$  from the trimer to hexamer), in general, with increasing chain length of oligonucleotide (Table 2). Interestingly, a simple comparison of  $\Delta\delta_{(N-D)}$  for H8G of 9-guaninyl in GpC ( $pK_a$  9.57) and GpA ( $pK_a$  9.17) shows (Figure 3) how the nearest neighbor (pC vs pA) modulates the pseudoaromaticity of the 9-guaninyl in the neutral ( $\delta$ H8G: 8.039 for GpC and 7.906 for GpA) and anionic form ( $\delta$ H8G: 7.862 for GpC and 7.765 for GpA). (b) *Comparison of  $\delta$  among Trimers to Hexamer:* Comparison of  $\Delta\delta_{(N-D)}$  for pA<sup>1</sup>p in GpA<sup>1</sup>pA and GpA<sup>1</sup>pA<sup>2</sup>pC shows the effect of 3'-terminal 1-cytosinyl of pC on the electronic makeup of pA<sup>1</sup>p. Similar comparison of  $\Delta\delta_{(N-D)}$  for pA<sup>1</sup>p in GpA<sup>1</sup>pA and GpA<sup>1</sup>pC shows the effect of the nearest neighbor at 3'-end (pC vs pA) on the chemical environment of pA<sup>1</sup>p. A comparison of  $\Delta\delta_{(N-D)}$  for pA<sup>1</sup>p and pA<sup>2</sup>p also shows that the relative effect of anionic 9-guaninyl remains to be almost the same in tetramer (GpA<sup>1</sup>pA<sup>2</sup>pC) and pentamer (GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pC) relative to the trimers GpA<sup>1</sup>pA (**4**) and GpApC (**5**). The effect of 9-guaninyl ion is considerably reduced in the hexamer **8**. This is because the intramolecular offset stacking through atom- $\pi\sigma$  interaction that opposes the anion- $\pi$ /dipole interaction is strongest in the hexamer **8** in our series of oligomers studied, which is evidenced by a relatively much smaller change in chemical shifts [ $\Delta\delta_{(N-D)}$ ] of all marker protons of all neighboring nucleobases in the former compared to the latter (Figure 3). This means that the electrostatic interaction of 9-guaninyl ion with the neighboring nucleobases tends to be minimal after the pA<sup>2</sup>p moiety in the hexamer (clearly detectable up to pA<sup>3</sup>p in pentamer **7** in comparison with the hexamer **8**, Figure 3). This also means that the pseudoaromaticity of the triplet codon, independent of the RNA chain length, is maximally cross-modulated owing to their full electronic coupling with the nearest neighbor. Clearly, the last three nucleobases at the 3'-end of the hexamer **8** are sensing the electrostatic interaction owing to the anionic character of 9-guaninyl moiety to a much lesser extent (ca. 10–15%) compared to the first two nucleobases after 5'-Gp anion. This is because of the fact that the attractive Coulombic forces stabilize the stacked state of the hexamer more efficiently than in the pentamer. As a result, this stabilizing atom- $\pi\sigma$  interaction counteracts the destabilizing anion- $\pi$  interaction more efficiently in the former than in the latter.

*Variable Electrostatic Effects of 3'- versus 5'-Phosphate.* Comparison of the  $pK_a$  of 9-guaninyl in GpEt (**1a**) ( $9.25 \pm 0.02$ )<sup>4d</sup> and EtpG (**1e**) ( $9.57 \pm 0.01$ ) shows (Table 1) that the 5'-phosphate in the latter makes the  $pK_a$  of 9-guaninyl more basic compared to the 3'-phosphate in the former. This is simply because of the fact that the spatial proximity of the 5'-phosphate and the imidazole moiety of the 9-guaninyl (in the anti conformation) in EtpG produces an effective electrostatic repulsion of their electron clouds, which enhances the electron density in the fused pyrimidine moiety, giving an overall increase of  $pK_a$  of 9-guaninyl in EtpG (**1e**) compared to that of GpEt (**1a**). It is, therefore, likely that the relative spatial orientation of the phosphates vs nucleobases may have a critical role in steering the  $pK_a$  and hence the chemical reactivity of purine nucleobases in ssRNA.

(ii) *Different  $pK_a$  Shift of Nucleobases due to Nearest-Neighbor Electrostatic Effect.* The pairwise comparison at the dimer level, however, shows (Table 1) that the  $pK_a$  of N<sup>1</sup>-H of 9-guaninyl residue in the GpA (**2a**)<sup>4d</sup> ( $9.17 \pm 0.02$ )/GpC (**3a**) ( $9.56 \pm 0.01$ ) ( $\Delta pK_a \pm 0.41$ ) is sequence dependent since the two isomeric dimers have the same phosphate charge but different 3'-nucleobase. Even at the trimer level,<sup>4c</sup> the comparison of GpApA (**4**) and GpApC (**5**) shows that although they have the same phosphate charge there is a slight difference in the  $pK_a$  of the 9-guaninyl residue ( $\Delta pK_a \pm 0.13$ , which is well above the error limit, Table 1). This suggests that the chemical nature of the nucleobase steers the  $pK_a$  of the nearest-neighbor nucleobase(s) more effectively than the phosphates.

<sup>a</sup> All  $pK_a$  values and their corresponding errors have been calculated from Hill plot analyses (See Figure 1 for the titration plots and Figure S2 in the Supporting Information for details of Hill plot analyses). <sup>b</sup> The free energy of deprotonation ( $\Delta G_{pK_a}^{\circ}$ , in  $\text{kJ mol}^{-1}$ ) of guanine-9-yl for compounds 1–8 has been calculated using the equation<sup>14a–c,f–i</sup>  $\Delta G_{pK_a}^{\circ} = 2.303RTpK_a$ . Similarly,  $\Delta \Delta G_{pK_a}^{\circ}$  (in  $\text{kJ mol}^{-1}$ ) values have been calculated using relation  $\Delta \Delta G_{pK_a}^{\circ} = 2.303RT\Delta pK_a$  where  $\Delta pK_a = [pK_a]_{\text{obtained from each residue}} - [pK_a]_{\text{1a and/or 1e}}$ . <sup>c</sup> Data have been taken from refs 4d,e. <sup>d</sup> No titration plot observed. The chemical shift difference over the pH range [ $\Delta\delta_{N-D}$ , in ppm] was much closer to the error limit (see Figures 2 and 3). Thus, no  $pK_a$ ,  $\Delta G_{pK_a}^{\circ}$  and  $\Delta \Delta G_{pK_a}^{\circ}$  have been calculated. <sup>e</sup> For  $\delta H5C$ . <sup>f</sup> For  $\delta H6C$ .

(iii) Comparison of  $\Delta G_{pK_a}^{\circ}$  of Different Marker Protons Shows Different Pseudoaromatic Character of the Neighboring Nucleobases. The  $\Delta G_{pK_a}^{\circ}$ <sup>14a–c,f–i</sup> for 9-guanylyl from different aromatic marker protons of the neighboring nucleobases varies (Table 1) from  $55.6 \pm 0.1$  to  $56.0 \pm 0.1$   $\text{kJ mol}^{-1}$  for **G<sup>-</sup>pApA (4)**,<sup>4e</sup>  $56.4 \pm 0.1$   $\text{kJ mol}^{-1}$  for **G<sup>-</sup>pApC (5)**,<sup>4e</sup>  $55.3 \pm 0.1$  to  $56.2 \pm 0.1$   $\text{kJ mol}^{-1}$  for **G<sup>-</sup>pApApC (6)**,  $54.7 \pm 0.2$  to  $57.5 \pm 0.2$   $\text{kJ mol}^{-1}$  for **G<sup>-</sup>pApApApC (7)**, and  $55.1 \pm 0.1$  to  $59.9 \pm 0.7$   $\text{kJ mol}^{-1}$  for **G<sup>-</sup>pApApApApC (8)**. These values should be compared with the  $\Delta G_{pK_a}^{\circ}$  of  $52.8 \pm 0.1$   $\text{kJ mol}^{-1}$  for **G<sup>-</sup>pEt (1a)**,<sup>4d</sup>  $52.4 \pm 0.1$   $\text{kJ mol}^{-1}$  for **G<sup>-</sup>pA (2a)**,<sup>4d</sup> and  $53.9 \pm 0.1$   $\text{kJ mol}^{-1}$  for of **CpG<sup>-</sup> (3b)**.

The  $\Delta G_{pK_a}^{\circ}$  for 9-guanylyl obtained from any other marker protons (H8A/H2A or H5/H6C) of the neighboring nucleobases within any single oligo-RNA **2a–8** ( $52–59.9$   $\text{kJ mol}^{-1}$ ) is

variable in a sequence-specific manner owing to different electronic coupling between any two next neighbors (Table 1). The lowering of the  $pK_a$  value obtained from a given marker proton (i.e., from  $\delta H8A$ ,  $\delta H2A$ , or  $\delta H5/H6C$ ) of a nucleobase relative to 9-guanylyl (i.e., from  $\delta H8G$ ) in a given oligo-RNA suggests a higher electrostatic screening. On the other hand, an increase of the  $pK_a$  value found from a marker proton of a nucleobase relative to 9-guanylyl in a given oligo-RNA suggests an added electronic contribution from those nucleobases themselves owing to their specific pseudoaromatic character orchestrated by the change of the local microenvironment.

The differences in  $\Delta G_{pK_a}^{\circ}$ <sup>14a–c,f–i</sup> from 9-guanylyl with respect to the monomeric **GpEt (1a)** or **5'-EtpG (1e)** (i.e.,  $\Delta \Delta G_{pK_a}^{\circ}$ ) is a measure of the relative stability of the 9-guanylate ion in the stacked vs destacked state (Table 1) owing to

variable efficiency of the electrostatic interactions (from  $-1.1$  to  $3.6$   $\text{kJ mol}^{-1}$  in **2a–8**). On the other hand, the  $\Delta G_{pK_a}^\circ$  for 9-guaninyl from the marker protons of other nucleobases show the subsequent electrostatic modulation ( $\Delta\Delta G_{pK_a}^\circ \approx -0.9$  to  $7.1$   $\text{kJ mol}^{-1}$ ), depending upon the sequence context as well as the number of phosphates (chain length) of the oligo-RNA chain. The  $\Delta G_{pK_a}^\circ$  is always larger ( $\Delta\Delta G_{pK_a}^\circ > 0$ ) in all residues of oligo-RNA than the monomeric GpEt (**1a**) (Table 1) with the exception of GpA (**2a**)<sup>4d</sup> as well as for pG of ApG (**2b**) and CpG (**3b**).

The fact that the  $pK_a$  (Table 1) of 5'-Gp residue can be measured from its own marker proton as well as from the other marker protons of the neighboring residues in ssRNA shows that the constituent nucleobases in the hexamer **8** (in which the first to sixth nucleotide residue is  $\sim 21\text{\AA}$  apart in the unfolded state), as well as in the dimers, trimers, tetramer, and pentamer **2a–7**, are electronically coupled because of the offset stacking. This enables each nucleobase in the chain to engage with the next neighbor(s) through a variable electrostatic interaction, depending upon their individual pseudoaromatic characters modulated by their respective microenvironments.<sup>4e</sup>

**(D) Mechanism of Interplay of Electrostatic Interactions in ssRNA.** The aromatic interactions<sup>5–9</sup> involved among the nearest-neighbor nucleobases in our oligo-RNA system are more complex in nature compared to that observed in nonbiological molecules<sup>5–7</sup> containing simple aryl systems such as phenyl<sup>6e,f</sup> or naphthyl.<sup>6g</sup> The attractive atom- $\pi\sigma$  interaction<sup>5</sup> in the offset stacked geometry exists among the neutral 9-guaninyl and neighboring 9-adeninyl, between 9-adeninyl and 9-adeninyl, as well as between 9-adeninyl and 1-cytosinyl (3'-end) in the tetrameric, pentameric, and hexameric RNAs, as originally observed by us for the dimeric<sup>4d</sup> and trimeric<sup>4e</sup> RNAs.

(i) *Participants in the Electrostatic Cross-Modulation in RNA.* Under quasiphysiological conditions, we have an electrostatic interplay between different electron clouds of various pseudoaromatic nucleobases which are modulated by the phosphate and the 2'-OH. In contrast, the electronic factors that contribute to the microenvironmental changes in our oligo-RNAs under alkaline pH are the mutual interactions and interplay of four electron-rich partners: (i) phosphates, (ii) the vicinal 2'-OH (free or intra- or intermolecularly hydrogen-bonded), (iii) guanylate ion, and (iv) different pseudoaromatic nucleobases.

Clearly, the observed  $\Delta G_{pK_a}^\circ$  from each marker proton in our ssRNA has, however, two contributors: (1) the electronic contribution from the specific pseudoaromatic character of each nucleobase (Q) (i.e., their relative electron-rich or electron-deficient character,  $[\Delta G_{pK_a}^\circ]_{\text{marker proton of Q}} - [\Delta G_{pK_a}^\circ]_{\text{(H8G from the ssRNA)}}$ ), and (2) the  $\Delta G_{pK_a}^\circ$  of 9-guaninyl itself (**Type 1** effect,<sup>4e</sup> which is  $[\Delta G_{pK_a}^\circ]_{\text{(H8G)}}$ ). These two contributing terms [(1) + (2)] together define the specific free-energy difference (**Type 2** effect<sup>4e</sup>) of the two-state protonation  $\rightleftharpoons$  deprotonation equilibrium of 9-guaninyl, which is observed in each of the *other* aromatic marker protons in the RNA molecule. Hence, the number of  $\Delta G_{pK_a}^\circ$  can be as high as the number of marker protons available in an oligo-RNA because of their different chemical nature and also depending upon how the edges of the nucleobases sense the immediate chemical microenvironment around them. This variation of immediate chemical microenvironment modulates (polarize) the electron

distribution of the offset stacked nucleobases, which is manifested in the observed variation  $pK_a$ s of 9-guaninyl from different marker protons within the hexamer ( $\Delta pK_a \pm 0.9$ ,  $\Delta\Delta G_{pK_a}^\circ \approx 5.1$   $\text{kJ mol}^{-1}$ ) and pentamer ( $\Delta pK_a \pm 0.48$ ,  $\Delta\Delta G_{pK_a}^\circ \approx 2.6$   $\text{kJ mol}^{-1}$ ).

(ii) *Origin of Atom- $\pi\sigma$  and Anion( $G^-$ )-Purine- $\pi$ /Dipole Interactions.* We considered both atom- $\pi\sigma$ <sup>5</sup> and the anion( $G^-$ )-purine- $\pi$ /dipole interactions in order to explain the observed electrostatic interaction<sup>4f,9</sup> for tetrameric, pentameric, and hexameric RNAs across the pH range of 7–12. The interaction between the 9-guanylate ion and the neighboring 9-adeninyl system is complex because of the fact that a 9-adeninyl moiety, consisting of electron-rich imidazole ( $\text{Im}^{\delta-}$ ) fused with the electron-deficient pyrimidine ( $\text{Py}^{\delta+}$ ) system, has a permanent dipole ( $\pi$ /dipole) ( $\mu \pm 3.0\text{--}3.7$  D).<sup>14d</sup> This means that the electrostatic interaction between the neighboring 9-guanylate ion and 9-adeninyl can either be *repulsive* anion( $G^-$ )- $\pi$ /dipole( $\text{Im}^{\delta-}$ ) or *attractive* anion( $G^-$ )- $\pi$ /dipole( $\text{Py}^{\delta+}$ ) interaction, depending upon their relative orientation. The relative chemical shift differences [ $\Delta\delta_{\text{(N-D)}}$ ] of protons of various nucleotide residues in the oligo-RNAs between the neutral (N) and the deprotonated (D) states of 5'-Gp residue here show (Figure 3) (i) how far the electrostatic anion( $G^-$ )- $\pi$ /dipole- ( $\text{Im}^{\delta-}$ ) interactions propagate along the RNA chain and (ii) how the interplay of the stabilizing atom- $\pi\sigma$  and anion( $G^-$ )- $\pi$ /dipole( $\text{Py}^{\delta+}$ ) interactions vs the destabilizing anion( $G^-$ )- $\pi$ /dipole( $\text{Im}^{\delta-}$ ) interaction dictate the two-state stacking  $\rightleftharpoons$  destacking equilibria as a function of pH<sup>13e</sup> along the RNA chain. In this connection, it should be emphasized that the  $\delta\text{H8}$  (marker for the imidazole part of the 9-adeninyl) suffers larger deshielding upon deprotonation because of destacking owing to repulsive anion( $G^-$ )- $\pi$ /dipole( $\text{Im}^{\delta-}$ ) interactions, whereas  $\delta\text{H2}$  (marker for the pyrimidine part of the 9-adeninyl) shows only shielding in the D state because of the attractive anion( $G^-$ )- $\pi$ /dipole( $\text{Py}^{\delta+}$ ) interaction.

(iii) *Effect of Atom- $\pi\sigma$  and Anion( $G^-$ )-Purine- $\pi$ /Dipole Interactions.* The implication of generating a negatively charged center, upon  $N^1$  deprotonation of 9-guaninyl residue, is that the nucleobases in the ssRNA chain become partially electronically decoupled (destacked), which is evidenced by the destabilization of the helix, compared to that in the neutral state (Figure 3). Comparison of the relative  $\delta\text{H8}$  shift (Table 2) as well as the relative magnitude of  $\Delta\delta_{\text{(N-D)}}$  of all aromatic protons in Figure 3, however, shows that the extent of this electrostatic promoted decoupling/destacking within the ssRNA helix is distance-dependent. This demonstrates that the effect of 9-guanylate charge at the 5'-terminus is perhaps largest until the third nucleobase, and then this effect is felt less and less as the distance between this charge and a given nucleobase increases in the helix.

As the pH becomes alkaline, the phosphate being negatively charged should repel the negatively charged guanylate anion. The alignment of all other nucleobases in the RNA sequence should be dictated by the guanylate-phosphate repulsion, which will be further modulated in a variable manner depending upon the individual pseudoaromatic character of the nucleobases. This may initiate a new stacking orientation and/or planar nucleobase rotation, which would steer the two-state stacking  $\rightleftharpoons$  destacking equilibria to a relatively more destacked state, causing a destabilization of the ssRNA helix. This destabilization of the

<sup>a</sup> The chemical shifts at the deprotonated (D) state are given in italics. All chemical shifts are measured with respect to internal standard DSS ( $\delta_{\text{DSS}} = 0.015$  ppm). See the Experimental Section for details. <sup>b</sup> Data are taken from refs 4d,e.

helix dictates a change of relative shielding or deshielding of a specific marker proton owing to the reorientation of the stacking geometry of the nearest neighbor(s). This may be the reason when H8A becomes deshielded, H2A responds by slight shielding by simple syn  $\rightleftharpoons$  anti shift of the glycosyl torsion. Clearly, in the absence of the vicinal 3-bond coupling constant data for the torsional angles of the sugar–phosphate backbone or the dipolar coupling data for deriving the relative orientation of the RNA molecule at the neutral versus deprotonated state, it is simply not possible to differentiate this pH-dependent geometrical change in any exact terms.

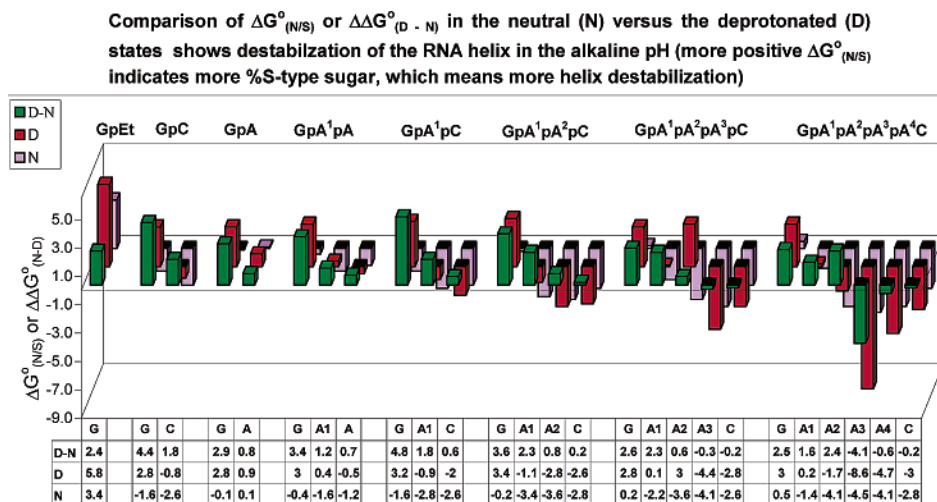

(iv) *Destabilization of ssRNA Helix in Alkaline pH Has Two Indicators: More Positive  $\Delta G_{\text{North/South}}^{\circ(298\text{K})}$  and Relative Deshielding of H8A.* It is well-known<sup>1a</sup> that in stacked helical oligo-RNA (i) the overall conformation of the sugar moieties is 3'-endo-2'-exo (North-type) because this allows nucleobases to be pseudoaxial,<sup>11c</sup> thereby bringing them in closer spatial proximity (3–3.5 Å) to be electronically coupled<sup>4d,e</sup> with the nearest neighbor, and (ii) the aromatic ring current of a given heterocycle has a shielding effect on the protons of the adjacent stacked heterocycle. Upon destabilization<sup>4d,e,13b–d</sup> of stacking in oligo-RNA, the reversal of this process has been found to take place in a dynamic manner<sup>11c</sup> in that an increase of the South(S)-type pseudorotamer population over the North(N)-type as well as a deshielding of the aromatic protons are observed. In a similar manner, concurrent with the deshielding of H8A proton in the alkaline pH compared to the neutral counterpart, we also observe a shift of the 3'-endo-2'-exo (North-type)  $\rightleftharpoons$  2'-endo-3'-exo (South-type) equilibrium [ $\Delta G_{\text{North/South}}^{\circ(298\text{K})}$ ]<sup>11c</sup>

of individual sugar units (see Figures 4 and 5) to the more South-type conformation in the deprotonated oligo-RNAs, thereby confirming that the destabilization of the stacked RNA helix indeed takes place in alkaline pH as a result of the guanylate ion formation.

Hence, in the case of pentameric and hexameric RNA, it is correct to say that the H8A deshielding in the alkaline pH is synonymous of the lost stability of stacking as evident from the  $\Delta G_{\text{North/South}}^{\circ(298\text{K})}$  shift in favor of the S-type conformation.

The  $\Delta\Delta G_{\text{D-N}}^{\circ(298\text{K})}$  values in Figure 5 also show that the destacking takes place more efficiently up to the third nucleotidic residue (from the 5'-end), and then it gradually decreases from the pA<sup>3</sup>p to pC-3' in GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pC (7) and pA<sup>4</sup>p to pC-3' in GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pA<sup>4</sup>pC (8).

(v) *Why Does the Destacking in Alkaline pH Become Less and Less Prominent as the ssRNA Chain Length Increases?* The strength of the stacking in ssRNA increases as the chain length increases, and hence, the  $\delta\text{H8/H2}$  of 9-adeninyl and  $\delta\text{H5/H6}$  of 1-cytosinyl moieties are more shielded in oligo-RNAs 2–8 (Table 2) in the N state, just as the H8G, compared to their monomeric counterpart.<sup>15b</sup> On the other hand, the  $\Delta\delta_{\text{(N-D)}}$  shows that the relative shielding of H8/H2A as well as H5/6C protons (with much less pronounced change for H8G) in the D state becomes less and less as the chain length increases as a result of a shift of the two-state stacking  $\rightleftharpoons$  destacking equilibrium<sup>11c,13e</sup> toward a destacked state (predominantly up to third nucleobase). Thus, the relative  $\Delta\delta_{\text{(N-D)}}$  for all aromatic marker protons except H8G (Figure 3) decreases in the following order: GpC < GpApC < GpApApC < GpApApApC < GpApApApApC.

**Figure 5.** Free energy [ $\Delta G^{\circ}_{\text{North/South}(298\text{K})}$ ] in  $\text{kJ mol}^{-1}$  represented in the figure as  $\Delta G^{\circ}_{(N/S)}$  estimations for the 3'-endo-2'-exo (North-type)  $\rightleftharpoons$  2'-endo-3'-exo (South-type) pseudorotational equilibrium<sup>12</sup> for the respective pentofuranose moiety in each nucleotidic unit in GpEt (**1a**), GpA (**2a**), GpC (**3a**), GpApC (**5**), GpA<sup>1</sup>pA<sup>2</sup>pC (**6**), GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pC (**7**), and GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pA<sup>4</sup>pC (**8**) at the neutral (N, shown in violet bar) and deprotonated (D, shown in red bar) states (see the table below the plot for  $\Delta G^{\circ}_{\text{North/South}(298\text{K})}$  values at N and D states as well as the difference between these two states, i.e., D-N). The free-energy values have been calculated using Gibbs relation:  $\Delta G^{\circ}_{\text{North/South}(298\text{K})} = -RT \ln K$ , where  $K = (x_N/x_S)$  and  $T = 298\text{ K}$  (See the Experimental Section and Figure 4 for details of the thermodynamic calculations).  $\Delta\Delta G^{\circ}_{D-N(298\text{K})}$  values have been calculated using the relation  $[\Delta G^{\circ}_{\text{North/South}(298\text{K})}]_D - [\Delta G^{\circ}_{\text{North/South}(298\text{K})}]_N = \Delta\Delta G^{\circ}_{D-N(298\text{K})}$ . The bars are in the same order as the sequence starting from 5'-Gp on the left. The difference between the D and the N states (D-N, shown in green) shows the relative stacking (negative free energy) or destacking (positive free energy) over the pH-titration range. It can be seen from D-N values that, upon generation of the 5'-guanylate ion, the destacking takes place until the third nucleotide in the hexa-, tetra-, and pentamer (compare with the more sensitive  $\Delta\delta_{(N-D)}$  values in Figure 3).

This destabilization in the two-state stacking  $\rightleftharpoons$  destacking equilibrium (that is the shift toward destacking) is becoming less and less effective because the repulsive anion( $G^-$ )-dipole-( $\text{Im}^{\delta-}$ ) interactions are counteracted more and more steadily by the attractive atom- $\pi\sigma$  and anion( $G^-$ )- $\pi$ /dipole( $\text{Py}^{\delta+}$ ) interactions as the RNA chain length increases. This is indeed evidenced by the fact that not only the terminal 1-cytosinyl of pC, but also the 9-adeninyl of the immediate neighbor pA<sup>1</sup>p (comparing GpApC with tetramer, pentamer, and hexamer) or pA<sup>2</sup>p (comparing pentamer and hexamer) showed reduced  $\Delta\delta_{(N-D)}$  (for  $\delta\text{H8A}$ ) with increase of the RNA chain length.

Thus, the basis for the observation of the titration curve of the marker protons (H8, H2, and H5/H6) is a pH-dependent response of the relative destacking or the stacking process as a result of competing electrostatic interactions through the ssRNA helix.

It is noteworthy that even in the dimers,<sup>4d</sup> such GpA (**2a**) or ApG (**2b**), the generation of 9-guanylate ion causes a general deshielding [ $\Delta\delta_{(N-D)}$ ] of the H8 proton (and  $\delta\text{H2}$  is non-responding) of the neighboring 9-adeninyl group, which suggests that a destacking due to the Coulombic repulsive anion( $G^-$ )-dipole( $\text{Im}^{\delta-}$ ) interaction has taken place in the alkaline pH.

Comparison<sup>19</sup> of oligomerization shift in N and D states of the oligo-RNA with respect to the appropriate monomeric units (**1a-g**) shows that as the stacking increases, the anion( $G^-$ )- $\pi$ /dipole( $\text{Im}^{\delta-}$ ) interaction becomes weaker (Tables S1 and S2 in Supporting Information).

## Conclusions

(1) The pseudoaromatic nucleobases in the hexameric RNA **8** as well as other oligo-RNAs **4-7** constitute an electronically coupled heterocyclic system right across the pH range, 6.7-12.1. The specific generation of a single guanylate ion in the

hexameric RNA molecule allowed us to demonstrate that the electrostatic atom- $\pi\sigma$  interaction indeed extends from the first to sixth nucleotide in a single-stranded hexameric RNA in the neutral state. This also shows that the strength of the stabilizing stacking interaction is strongest under the quasi-physiological condition at the neutral state. The transmission of  $\Delta G^{\circ}_{pK_a}$  from the 5'-guanine-9-yl (or 9-guanylate ion) to the 3'-end nucleobase in the hexameric RNA **8** shows the cross-modulation of the pseudoaromatic character of the nearest neighbors by electrostatic interaction.

(2) The stability of the stacked helical RNA conformation is reduced by the destabilizing anion( $G^-$ )- $\pi$ /dipole( $\text{Im}^{\delta-}$ ) interaction as a result of the generation of the 9-guanylate ion. This destabilizing effect in the deprotonated RNA becomes less pronounced as the RNA chain length increases because of opposing atom- $\pi\sigma$  interaction (major) as well as minor anion( $G^-$ )- $\pi$ /dipole( $\text{Py}^{\delta+}$ ) interactions. This is quite similar to the polar- $\pi$  effect found between ions and arene,<sup>7e,f</sup> such as carboxylate-arene interactions<sup>7f</sup> and trimethylammonium ion-arene interactions.<sup>7e</sup> The 9-guanylate ion has a maximal destack-

(19) At the neutral pH, the difference of magnetic shielding ( $\Delta\delta_{N(M-O)} > 0$ ) found in oligomers (*O*) with respect to the monomers (*M*), GpEt (**1a**) and EtpApEt (**1f**) and EtpC (**1g**), results from the cross-modulation of the pseudoaromatic character owing to the offset-stacked coupled aromatic heterocycles within a polyanionic sugar-phosphate backbone. Comparison of  $\Delta\delta_{N(M-O)}$  and  $\Delta\delta_{D(M-O)}$  as well as of  $\Delta\delta_{(N-D)}$  for cytosin-1-yl (pC) at the 3'-terminal showed that the stacking propensity of pC increases with the chain length (Tables S1 and S2 in the Supporting Information), having maximal upfield shift in the hexameric-RNA at both the neutral as well as in deprotonated states. Similarly, the stacking propensity of the pA<sup>2</sup>p and pA<sup>3</sup>p also increases for hexameric-RNA compared to pentameric-RNA (**7** and **8**) as a function of pH, which is consistent with the observed reduction of  $\Delta\delta_{(N-D)}$ . It is noteworthy that the relative stacking abilities of **2-8** are reduced at the deprotonated state compared to that in the neutral state [ $\Delta\delta_{N(M-O)} > \Delta\delta_{D(M-O)}$ ], decrease of  $\Delta\Delta\delta_{N-D}^{M-O}$  from **2** to **8**, Tables S1 and S2 in the Supporting Information]. It, therefore, shows that the stabilizing offset stacking through electrostatic atom- $\pi\sigma$  and ion-dipole interactions increases most in the hexameric-RNA, which means that the stacking in hexamer opposes the anion( $G^-$ )- $\pi$ /dipole( $\text{Im}^{\delta-}$ ) interaction (causing destacking) more efficiently than in the dimeric-, trimeric-, tetrameric-, or pentameric-RNA.

ing effect up to the third nucleobase along the ssRNA chain, and then the effect diminishes considerably.

(3) The magnitude of the chemical shift change in any of the aromatic protons in either of the two coupled nucleobases differs in a variable manner depending upon the geometry of stacking, electron density around the heteroatom, as well as the sequence context, which is evident from the relative chemical shift changes of the aromatic marker protons as well as from their comparison with the monomeric units. Thus, the physicochemical character (i.e., the cross-modulation of pseudoaromaticity) of an individual nucleobase in an oligonucleotide is determined in a tunable manner, depending upon both the geometry and the strength of the nearest-neighbor interaction.

(4) The pH titration studies with the GpA<sup>1</sup>pA<sup>2</sup>pA<sup>3</sup>pA<sup>4</sup>pC (8) showed that the pK<sub>a</sub> of N<sup>1</sup>-H of 9-guaninyl from its own δH8G (pK<sub>a</sub> 9.76 ± 0.01), δH8A<sup>1</sup> (pK<sub>a</sub> 9.65 ± 0.01), and δH2A<sup>1</sup> (pK<sub>a</sub> 9.80 ± 0.01) of the pA<sup>1</sup>p moiety, δH8A<sup>2</sup> (pK<sub>a</sub> 9.95 ± 0.01) and δH2A<sup>2</sup> (pK<sub>a</sub> 10.5 ± 0.07) of the pA<sup>2</sup>p moiety, δH2A<sup>4</sup> (pK<sub>a</sub> 9.66 ± 0.01) of pA<sup>4</sup>p moiety, and δH6C (pK<sub>a</sub> 10.18 ± 0.03) of the terminal pC-3' moiety. Thus, the pK<sub>a</sub> of 5'-Gp residue from its own δH8G varies only slightly (from 9.76 ± 0.02 to 9.88 ± 0.01) in the oligo-RNAs 5–8, which should be compared with the pK<sub>a</sub> of 9.25 ± 0.01 for GpEt (1a), pK<sub>a</sub> of 9.17 ± 0.02 for GpA (2a), pK<sub>a</sub> of 9.56 ± 0.01 for GpC (3a), pK<sub>a</sub> of 9.45 ± 0.02 for CpG (3b), and pK<sub>a</sub> of 9.57 ± 0.01 for 5'-EtpG (3b). The variation of pK<sub>a</sub>s for 5'-Gp residue from *other* aromatic marker protons in the hexamer is, however, more pronounced (from 9.65 ± 0.02 to 10.5 ± 0.12) (Table 1). This variation of pK<sub>a</sub>s (ΔpK<sub>a</sub> ± 0.9) in the hexamer represents a ΔΔG<sub>pK<sub>a</sub></sub><sup>o</sup> of ca. 5.1 kJ mol<sup>-1</sup>, which has been attributed to the variable strength of electrostatic interactions<sup>4d,e</sup> between the electron densities of the involved atoms in the offset stacked nucleobases as well as with that of the phosphates.

(5) The net result of obtaining pK<sub>a</sub>s of a single ionization point from all marker protons of each nucleotide residue is that it allows us to experimentally examine the microscopic change of the electronic environment around each constituent nucleobase along the RNA chain in a stepwise manner with considerable accuracy without having to make any assumptions. Specific isotope labeling at various sites (i.e., nonuniform labeling) may help in solving the resonance overlapping problems while measuring the pH-dependent chemical shifts of larger biologically active oligo-RNA (depending upon its stability in the pH range to be studied) in understanding the RNA structure–function, in general.

(6) The ΔG<sub>pK<sub>a</sub></sub><sup>o</sup> for 9-guaninyl from different marker protons varies (Table 1) from 55.6 ± 0.1 to 56.0 ± 0.1 kJ mol<sup>-1</sup> for G<sup>-</sup>pApA (4),<sup>4e</sup> 56.4 ± 0.1 kJ mol<sup>-1</sup> for G<sup>-</sup>pApC (5),<sup>4e</sup> 55.3 ± 0.1 to 56.2 ± 0.1 kJ mol<sup>-1</sup> for G<sup>-</sup>pApApC (6), 54.7 ± 0.2 to 57.5 ± 0.2 kJ mol<sup>-1</sup> for G<sup>-</sup>pApApApC (7), and 55.1 ± 0.1 to 59.9 ± 0.7 kJ mol<sup>-1</sup> for G<sup>-</sup>pApApApApC (8). These values should be compared with the ΔG<sub>pK<sub>a</sub></sub><sup>o</sup> of 52.8 ± 0.1 kJ mol<sup>-1</sup> for G<sup>-</sup>pEt (1),<sup>4d</sup> 52.4 ± 0.1 kJ mol<sup>-1</sup> for G<sup>-</sup>pA (2),<sup>4d</sup> and 53.9 ± 0.1 kJ mol<sup>-1</sup> for CpG<sup>-</sup> (3b). The differences in ΔG<sub>pK<sub>a</sub></sub><sup>o</sup> measured<sup>14a,b,f-h</sup> from 9-guaninyl in 2–8 with respect to the monomeric GpEt (1a) or 5'-EtpG (1e) (i.e., ΔΔG<sub>pK<sub>a</sub></sub><sup>o</sup>) is a measure of the relative stability of the 9-guanilate ion in the stacked vs destacked state (Table 1) owing to the variable efficiency of the electrostatic interactions (from -1.1 to 3.6 kJ mol<sup>-1</sup>). On the other hand, the ΔG<sub>pK<sub>a</sub></sub><sup>o</sup> measured for 9-guaninyl

from the marker protons show the subsequent electrostatic modulation (ΔΔG<sub>pK<sub>a</sub></sub><sup>o</sup> ≈ -0.9 to 7.1 kJ mol<sup>-1</sup>), depending upon the sequence context as well as the number of phosphates (chain length) of the oligo-RNA chain. The ΔG<sub>pK<sub>a</sub></sub><sup>o</sup> is always larger (ΔΔG<sub>pK<sub>a</sub></sub><sup>o</sup> > 0) in all residues of oligo-RNA than the monomeric GpEt (1a) (Table 1) with the exception of GpA (2a)<sup>4d</sup> as well as pG of ApG (2b) and CpG (3b). This means that these additional electrostatic contributions originate from the specific chemical nature of the pseudoaromatic nucleobases of the immediate neighbors due to the change of the local electronic microenvironment, in addition to the charge of the 9-guanilate ion, thereby suggesting, for example, that the pseudoaromatic character of all 9-adeninyl groups in the hexamer is not the same.

## Implications

(1) The pH titration study offers an in depth understanding of the nature of the electrostatic mediated self-assembly process by simple intramolecular stacking interactions and the conformational dynamics in the single-stranded RNA, which are normally very difficult to quantitate by state-of-the-art NMR spectroscopy.

(2) The generation of a new anionic<sup>10</sup> or cationic<sup>7a-g</sup> center in the ssRNA destabilizes the stacked state in a distance-dependent manner, which can be thermodynamically described using our pH titration procedure. The fact that the pK<sub>a</sub> of 9-guaninyl can be observed from the marker protons of other neighboring residues in the hexamer shows that all residues in the hexamer are stacked (except pA<sup>3</sup>p), although stacking geometry cannot be elucidated, mainly because of inadequate NMR data. Since the pA<sup>3</sup>p residue in the hexamer did not respond to the titration; it shows that it is outside the stacking zone of the neighbors, perhaps bulged out and solvated. Thus, pH titration study with NMR in conjunction with structure elucidation by NMR/ab initio or X-ray and subsequent Poisson–Boltzmann calculation<sup>4j</sup> of the surface potential distribution may allow us to map the electrostatic effect in a ssRNA, in general.<sup>4h</sup> This may help us to understand why the sequence context is so important for biological recognition, interaction, and function of RNA in general.

(3) The sequence-dependent modulation of the pseudoaromatic character of the nucleobases in an oligo-RNA would change the ligand binding properties both by weak interactions (electrostatic, hydrophobic, van der Waals) as well as by hydrogen bonding interactions as found in the aptamers. We, however, envision that the spread of these electrostatic interactions along the RNA chain would depend on whether the neighboring nucleobases are electronically coupled owing to offset stacking or not (ON–OFF switch).

(4) This sequence-stacking based cross-modulation of the pseudoaromatic character to the nearest neighbor at the ground state is likely to be more pronounced in the helical double-stranded RNAs than in the ssRNA because of the restricted flexibility of the former.

## Experimental Section

(A) **pH-Dependent <sup>1</sup>H NMR Measurement.** All NMR experiments were performed in Bruker DRX-500 and DRX-600 spectrometers. The NMR samples for compounds 1–8 (Figure 1) were prepared in D<sub>2</sub>O solution (concentration of 1 mM in order to rule out any chemical shift change owing to self-association) with δ<sub>DSS</sub> = 0.015 ppm as internal

standard. All pH-dependent NMR measurements have been performed at 298 K. The pH values [with the correction of deuterium effect] correspond to the reading on a pH meter equipped with a calomel microelectrode (in order to measure the pH inside the NMR tube) calibrated with standard buffer solutions (in  $H_2O$ ) of pH 7 and 10. The pD of the sample has been adjusted by simple addition of microliter volumes of NaOD solutions (0.5, 0.1, and 0.01 M). The assignments for all compounds have been performed on the basis of selective homo- ( $^1H$ ) and heteronuclear ( $^{31}P$ ) decoupling experiments for **3a** as well as using  $^1H$  NOESY,  $^1H$  COSY,  $^{31}P$  decoupled  $^1H$  COSY, TOCSY, and  $^{31}P$ - $^1H$  correlation spectroscopy for **6-8** at 298 and 283 K at neutral pH (see Supporting Information). All  $^1H$  spectra have been recorded using 128 K data points and 64 scans. All NOESY spectra for **6-8** (see the Supporting Information for details) were recorded in a 600 MHz spectrometer with a mixing time ( $\tau_m$ ) of 800 ms. For each FID of NOESY,  $^1H$  DQF-COSY,  $^{31}P$  decoupled  $^1H$  DQF-COSY, and TOCSY spectra, 64 scans were recorded with a delay of 2s and the data were zero-filled to  $4 \times 1$  K in the  $t_1$  and  $t_2$  directions, then Fourier transformed, phase adjusted, and baseline corrected in both dimensions using polynomial function. The  $^{31}P$ - $^1H$  correlation spectroscopy experiment was performed in the absolute magnitude mode using 64 scans with a delay of 2s and then zero-filled to  $1 \times 1$  K data points in the  $t_1$  and  $t_2$  directions, then Fourier transformed, phase adjusted, and baseline corrected in both dimensions using polynomial functions.

**(B) pH Titration of Aromatic Protons in 1-8.** See refs 4c and 4d for details of the titration profile of GpEt (**1a**), GpA (**2a**), ApG (**2b**), GpA $^1$ pA (**4**), and GpApC (**5**). The pH titration studies (pH 6.9-12.1) for isomeric GpC (**3a**) and CpG (**3b**) consist of ~28 data points (see Figure 2). Similarly, the pH titration studies for GpA $^1$ pA $^2$ pC (**6**) (pH 7.1-11.8); GpA $^1$ pA $^2$ pA $^3$ pC (**7**) (pH 7.1-11.7), and GpA $^1$ pA $^2$ pA $^3$ pA $^4$ -pC (**8**) (pH 6.7-12.2) consist of ~25-33 data points (see Figure 2). The corresponding Hill plots for **3a**, **3b**, and **6-8** are given in the Supporting Information (Figure S1 in Supporting Information), and the  $pK_a$ s shown in Table 1 have been calculated from Hill plot analyses (see section C for details).

**(C)  $pK_a$  Determination.** The pH-dependent [over the range of pH 6.7-12.2, with an interval of pH 0.2-0.3]  $^1H$  chemical shift ( $\delta$ , with error  $\pm 0.001$  ppm) for **6-8** shows a sigmoidal (having an average of 20 different pH-dependent chemical shifts in each titration profile) behavior [Figure 2]. The  $pK_a$  determination is based on the Hill plot analysis<sup>11a,12b,14c</sup> using  $pH = \log((1 - \alpha)/\alpha) + pK_a$ , where  $\alpha$  represents a fraction of the protonated species. The value of  $\alpha$  is calculated from the change of chemical shift relative to the deprotonated (D) state at a given pH ( $\Delta_D = \delta_D - \delta_{obs}$  for deprotonation, where  $\delta_{obs}$  is the experimental chemical shift at a particular pH) divided by the total change in chemical shift between neutral (N) and deprotonated (D) state ( $\Delta_T$ ). Thus, the Henderson-Hasselbalch-type equation<sup>11a,14c</sup> can then be written as  $pH = \log((\Delta_T - \Delta_D)/\Delta_D) + pK_a$ . The  $pK_a$  is calculated from the linear regression analysis of the Hill plot [Figure S2 in Supporting Information].

**(D) pH-Dependent Sugar Conformation and Gibbs Free Energy [ $\Delta G^{\circ}_{North/South(298K)}$ ] Calculations.** The conformational analyses of the furanose moiety of **1a**, **2a**, **3a**, and **4-8** in the N and D states of the two-state 3'-endo-2'-exo (North-type)  $\rightleftharpoons$  2'-endo-3'-exo (South-type) pseudorotational equilibrium<sup>11</sup> have been performed by using the relation %North-type =  $100(7.9 - {}^3J_{1'2'})/6.9$ .<sup>11c</sup> Figure 4 shows the

bar plot of %North-type pseudorotamer population (error of  $\pm 2\%$ ) at the N and D states as well as their differences (D - N). The free energies [ $\Delta G^{\circ}_{North/South(298K)}$ , in  $kJ mol^{-1}$ ] have been calculated using Gibb's equation:  $\Delta G^{\circ}_{North/South(298K)} = -RT \ln K$ , where  $K = (x_{North}/x_{South})$ ;  $x_{North}$  and  $x_{South}$  are the mole fraction of North-type and South-type pseudorotamer, respectively. Hence, the negative  $\Delta G^{\circ}_{North/South(298K)}$  implies relatively more North-type conformational population, so more stabilization due to stacking<sup>4d,13b,d</sup> (see Table S3 in Supporting Information for  ${}^3J_{1'2'}$  values).

**(E) Calculations of the Dimerization and/or Oligomerization Shift.** Dimerization and/or oligomerization shifts<sup>13b</sup> are calculated for the individual nucleotide residues in a dimer (d) and/or oligomer (O) with respect to the monomeric (M) counterparts [ $\Delta\delta_{N(M-d)}$  and/or  $\Delta\delta_{N(M-O)}$  as well as  $\Delta\delta_{D(M-d)}$  and/or  $\Delta\delta_{D(M-O)}$ , respectively] at the neutral (N) and deprotonated (D) states.<sup>19</sup>
